# The Alpha and Beta of Stock Returns

The daily stock returns  $r_i - r_f$  in excess of the risk-free rate  $r_f$ , can be decomposed into *systematic* returns  $\beta(r_m - r_f)$  (where  $r_m - r_f$  are the excess market returns) plus *idiosyncratic* returns  $\alpha + \varepsilon_i$  (which are uncorrelated to the market returns):

$$r_i - r_f = \alpha + \beta(r_m - r_f) + \varepsilon_i$$

The *alpha*  $\alpha$  are the abnormal returns in excess of the risk premium, and  $\varepsilon_i$  are the regression residuals with zero mean.

The *idiosyncratic* risk (equal to  $\varepsilon_i$ ) is uncorrelated to the *systematic* risk, and can be reduced through portfolio diversification.

```
> # Perform regression using formula
> retp <- na.omit(rutils::etfenv$returns[, c("XLP", "VTI")])
> riskfree <- 0.03/252
> retp <- (retp - riskfree)
> regmod <- lm(XLP ~ VTI, data=retp)
> regmodsum <- summary(regmod)
> # Get regression coefficients
> coef(regmodsum)
              Estimate Std. Error t value Pr(>|t|)
(Intercept)  6.71e-05   8.37e-05   0.802   0.423
VTI          5.69e-01   6.80e-03  83.567   0.000
> # Get alpha and beta
> coef(regmodsum)[, 1]
(Intercept)      VTI
  6.71e-05    5.69e-01
```

```
> # Plot scatterplot of returns with aspect ratio 1
> plot(XLP ~ VTI, data=rutils::etfenv$returns, main="Regression XLP
+       xlim=c(-0.1, 0.1), ylim=c(-0.1, 0.1), pch=1, col="blue", asp=1)
> # Add regression line and perpendicular line
> abline(regmod, lwd=2, col="red")
> abline(a=0, b=-1/coef(regmodsum)[2, 1], lwd=2, col="blue")
```

# The Statistical Significance of $\alpha$ and $\beta$

The stock  $\beta$  is independent of the risk-free rate  $r_f$ :

$$\beta = \frac{\text{Cov}(r_i, r_m)}{\text{Var}(r_m)}$$

The  $t$ -statistic ( $t$ -value) is the ratio of the estimated value divided by its standard error.

The  $p$ -value is the probability of obtaining values exceeding the  $t$ -statistic, assuming the *null hypothesis* is true.

A small  $p$ -value means that the regression coefficients are very unlikely to be zero (given the data).

The  $\beta$  values of stock returns are very statistically significant, but the  $\alpha$  values are mostly not significant.

The  $p$ -value of the *Durbin-Watson* test is large, which indicates that the regression residuals are not autocorrelated.

In practice, the  $\alpha$ ,  $\beta$ , and the risk-free rate  $r_f$ , depend on the time interval of the data, so they're time dependent.

```
> # Get regression coefficients
> coef(regmodsum)
              Estimate Std. Error t value Pr(>|t|)
(Intercept) 6.71e-05   8.37e-05   0.802   0.423
VTI         5.69e-01   6.80e-03  83.567   0.000
> # Calculate regression coefficients from scratch
> betav <- drop(cov(retp$XLP, retp$VTI)/var(retp$VTI))
> alpha <- drop(mean(retp$XLP) - betav*mean(retp$VTI))
> c(alpha, betav)
[1] 6.71e-05 5.69e-01
> # Calculate the residuals
> residuals <- (retp$XLP - (alpha + betav*retp$VTI))
> # Calculate the standard deviation of residuals
> nrows <- NROW(residuals)
> residsd <- sqrt(sum(residuals^2)/(nrows - 2))
> # Calculate the standard errors of beta and alpha
> sum2 <- sum((retp$VTI - mean(retp$VTI))^2)
> betasd <- residsd/sqrt(sum2)
> alphasd <- residsd*sqrt(1/nrows + mean(retp$VTI)^2/sum2)
> c(alphasd, betasd)
[1] 8.37e-05 6.80e-03
> # Perform the Durbin-Watson test of autocorrelation of residuals
> lmtest::dwtest(regmod)
```

Durbin-Watson test

```
data: regmod
DW = 2, p-value = 1
alternative hypothesis: true autocorrelation is greater than 0
```

# The Alpha and Beta of ETF Returns

The *beta*  $\beta$  values of ETF returns are very statistically significant, but the *alpha*  $\alpha$  values are mostly not significant.

Some of the ETFs with significant *alpha*  $\alpha$  values are the bond ETFs *IEF* and *TLT* (which have performed very well), and the natural resource ETFs *USO* and *DBC* (which have performed very poorly).

```

# Capital Asset Pricing Model (CAPM)

The CAPM model states that the expected return for stock  $n$ :  $\mathbb{E}[R_n]$  is proportional to its beta  $\beta_n$  times the expected excess return of the market  $\mathbb{E}[R_m] - r_f$ :

$$\mathbb{E}[R_n] = r_f + \beta_n(\mathbb{E}[R_m] - r_f)$$

The CAPM model states that if a stock has a higher beta then it's also expected to earn higher returns.

According to the CAPM model, assets are on average expected to earn only a *systematic* return proportional to their *systematic* risk.

The CAPM model is not a regression model.

The CAPM model depends on the choice of the risk-free rate  $r_f$ .

```
> library(PerformanceAnalytics)
> # Calculate XLP beta
> PerformanceAnalytics::CAPM.beta(Ra=retp$XLP, Rb=retp$VTI)
[1] 0.569
> # Or
> retxlp <- na.omit(retp[, c("XLP", "VTI")])
> betav <- drop(cov(retxlp$XLP, retxlp$VTI)/var(retxlp$VTI))
> betav
[1] 0.569
> # Calculate XLP alpha
> PerformanceAnalytics::CAPM.alpha(Ra=retp$XLP, Rb=retp$VTI)

> # Calculate XLP bear beta
> PerformanceAnalytics::CAPM.beta.bear(Ra=retp$XLP, Rb=retp$VTI)
[1] 0.581
```

# The Security Market Line for ETFs

The *Security Market Line* (SML) represents the linear relationship between expected stock returns and their systematic risk  $\beta$ .

The SML depends on the choice of the risk-free rate  $r_f$ , with a steeper SML line for lower risk-free rates  $r_f$ .

All the different SML lines pass through the point ( $\beta = 1, r = R_m$ ) corresponding to the market, and they intersect the y-axis at the risk-free point ( $\beta = 0, r = r_f$ ).

A scatterplot of asset returns versus their  $\beta$  shows which assets earn a positive  $\alpha$ , and which don't.

If an asset lies on the SML, then its returns are mostly systematic, and its  $\alpha$  is equal to zero.

Assets above the SML have a positive  $\alpha$ , and those below have a negative  $\alpha$ .

```
> symbolv <- rownames(betam)
> betav <- betam[~match(c("VXX", "SVXY", "MTUM", "USMV", "QUAL"),
> betav <- c(1, betav)
> names(betav)[1] <- "VTI"

```

# Beta-adjusted Performance Measurement

The *Treynor* ratio measures the excess returns per unit of the *systematic* risk  $\beta$ , and is equal to the excess returns (over a risk-free return) divided by the  $\beta$ :

$$T_r = \frac{E[R - r_f]}{\beta}$$

The *Treynor* ratio is similar to the *Sharpe* ratio, with the difference that its denominator represents only *systematic* risk, not total risk.

The *Information* ratio is equal to the excess returns (over a benchmark) divided by the *tracking error* (standard deviation of excess returns):

$$I_r = \frac{E[R - R_b]}{\sqrt{\sum_{i=1}^n (R_i - R_{i,b})^2}}$$

The *Information* ratio measures the amount of outperformance versus the benchmark, and the consistency of outperformance.

```
> library(PerformanceAnalytics)
> # Calculate XLP Treynor ratio
> TreynorRatio(Ra=retp$XLP, Rb=retp$VTI)
[1] 0.098
> # Calculate XLP Information ratio

+   })).
```

# Recursive Trailing Stock Beta

The trailing beta  $\beta$  of a stock with returns  $r_t$  with respect to a stock index with returns  $R_t$  can be updated using these recursive formulas with the decay factor  $\lambda$ :

$$\bar{r}_t = \lambda \bar{r}_{t-1} + (1 - \lambda) r_t$$

$$\bar{R}_t = \lambda \bar{R}_{t-1} + (1 - \lambda) R_t$$

$$\sigma_t^2 = \lambda \sigma_{t-1}^2 + (1 - \lambda) (R_t - \bar{R}_t)^2$$

$$\text{cov}_t = \lambda \text{cov}_{t-1} + (1 - \lambda) (r_t - \bar{r}_t) (R_t - \bar{R}_t)$$

$$\beta_t = \frac{\text{cov}_t}{\sigma_t^2}$$

The parameter  $\lambda$  determines the rate of decay of the weight of past returns. If  $\lambda$  is close to 1 then the decay is weak and past returns have a greater weight, and the trailing mean values have a stronger dependence on past returns. This is equivalent to a long look-back interval. And vice versa if  $\lambda$  is close to 0.

The function `HighFreq::run_covar()` calculates the trailing variances and covariance of two *time series*.

```
> # Calculate the trailing betas
> lambda <- 0.99
> covarv <- HighFreq::run_covar(retp, lambda)
> betav <- covarv[, 1]/covarv[, 3]
```

```
> # dygraph plot of trailing XLP beta and VTI prices
> datav <- cbind(pricev, betav[endsd])[-(1:11)] # Remove warmup period
> colnames(datav)[2] <- "beta"
> colnamev <- colnames(datav)
> dygraphs::dygraph(datav, main="XLP Trailing 12-month Beta and VTI Prices")
+ dyAxis("y", label=colnamev[1], independentTicks=TRUE) %>%
+ dyAxis("y2", label=colnamev[2], independentTicks=TRUE) %>%
+ dySeries(name=colnamev[1], axis="y", col="blue", strokeWidth=2)
+ dySeries(name=colnamev[2], axis="y2", col="red", strokeWidth=2)
+ dyLegend(show="always", width=500)
```

# Principal Components of S&P500 Stock Constituents

The *PCA* standard deviations are the volatilities of the *principal component* time series.

The original time series of returns can be calculated approximately from the first few *principal components* with the largest standard deviations.

The *Kaiser-Guttman* rule uses only *principal components* with *variance* greater than 1.

Another rule of thumb is to use the *principal components* with the largest standard deviations which sum up to 80% of the total variance of returns.

Volatilities of S&P500 Principal Components

```
> # Load S&P500 constituent stock prices
> load("/Users/jerzy/Develop/lecture_slides/data/sp500_prices.RData")
> # Calculate stock prices and percentage returns
> pricets <- zoo::na.locf(pricets, na.rm=FALSE)
> pricets <- zoo::na.locf(pricets, fromLast=TRUE)
> retp <- rutils::diffit(log(pricev))
> # Standardize (de-mean and scale) the returns
> retp <- lapply(retp, function(x) {(x - mean(x))/sd(x)})
> retp <- rutils::do_call(cbind, retp)
> # Perform principal component analysis PCA
> pcad <- prcomp(retp, scale=TRUE)
> # Find number of components with variance greater than 2
> ncomp <- which(pcad$sdev^2 < 2)[1]
```

```
> # Plot standard deviations of principal components
> barplot(pcad$sdev[1:ncomp],
+   names.arg=colnames(pcad$rotation[, 1:ncomp]),
+   las=3, xlab="", ylab="",
+   main="Volatilities of S&P500 Principal Components")
```

# S&P500 Principal Component Loadings (Weights)

*Principal component loadings* are the weights of *principal component* portfolios.

The *principal component* portfolios have mutually orthogonal returns represent the different orthogonal modes of the return variance.

```
> # Calculate principal component loadings (weights)
> # Plot barplots with PCA weights in multiple panels
> ncomps <- 6
> par(mfrow=c(ncomps/2, 2))
> par(mar=c(4, 2, 2, 1), oma=c(0, 0, 0, 0))
> # First principal component weights
> weights <- sort(pcad$rotation[, 1], decreasing=TRUE)
> barplot(weights[1:6], las=3, xlab="", ylab="", main="")
> title(paste0("PC", 1), line=-2.0, col.main="red")
> for (ordern in 2:ncomps) {
+   weights <- sort(pcad$rotation[, ordern], decreasing=TRUE)
+   barplot(weights[c(1:3, 498:500)], las=3, xlab="", ylab="", main="")
+   title(paste0("PC", ordern), line=-2.0, col.main="red")
+ } # end for
```

# S&P500 Principal Component Time Series

The time series of the *principal components* can be calculated by multiplying the loadings (weights) times the original data.

Higher order *principal components* are gradually less volatile.

```
> # Calculate principal component time series
> retspca <- xts(retp %*% pcad$rotation[, 1:ncomps], order.by=datev)
> round(cov(retspca), 3)
> pcacum <- cumsum(retspca)
> # Plot principal component time series in multiple panels
> par(mfrow=c(ncomps/2, 2))
> par(mar=c(2, 2, 0, 1), oma=c(0, 0, 0, 0))
> rangev <- range(pcacum)
> for (ordern in 1:ncomps) {
+   plot.zoo(pcacum[, ordern], ylim=rangev, xlab="", ylab="")
+   title(paste0("PC", ordern), line=-2.0)
+ } # end for
```

# S&P500 Factor Model From Principal Components

By inverting the *PCA* analysis, the *S&P500* constituent returns can be calculated from the first  $k$  *principal components* under a *factor model*:

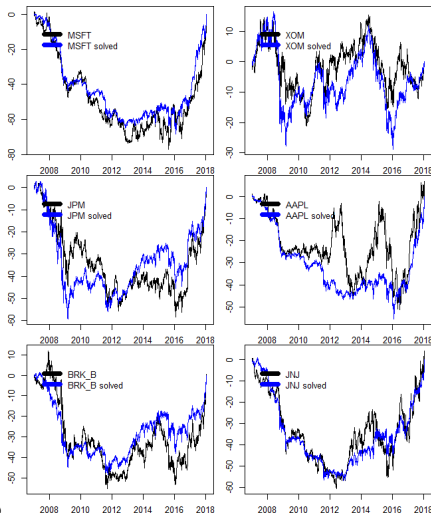

$$\mathbf{r}_i = \alpha_i + \sum_{j=1}^k \beta_{ji} \mathbf{F}_j + \varepsilon_i$$

The *principal components* are interpreted as *market factors*:  $\mathbf{F}_j = \mathbf{pc}_j$ .

The *market betas* are the inverse of the *principal component loadings*:  $\beta_{ji} = w_{ij}$ .

The  $\varepsilon_i$  are the *idiosyncratic* returns, which should be mutually independent and uncorrelated to the *market factor* returns.

```
> # Invert principal component time series
> invmat <- solve(pcad$rotation)
> all.equal(invmat, t(pcad$rotation))
> solved <- retspca %*% invmat[1:ncomps, ]
> solved <- xts::xts(solved, datev)
> solved <- cumsum(solved)
> retc <- cumsum(retp)
> # Plot the solved returns
> symbolv <- c("MSFT", "XOM", "JPM", "AAPL", "BRK_B", "JNJ")
> for (symbol in symbolv) {
+   plot.zoo(cbind(retc[, symbol], solved[, symbol]),
+   plot.type="single", col=c("black", "blue"), xlab="", ylab="")
+   legend(x="topleft", bty="n",
+   legend=paste0(symbol, c("", " solved")),
+   title=NULL, inset=0.05, cex=1.0, lwd=6,
+   lty=1, col=c("black", "blue"))
+ } # end for
```

# S&P500 Factor Model Residuals

The original time series of returns can be calculated exactly from the time series of all the *principal components*, by inverting the loadings matrix.

The original time series of returns can be calculated approximately from just the first few *principal components*, which demonstrates that *PCA* is a form of *dimension reduction*.

The function `solve()` solves systems of linear equations, and also inverts square matrices.

```
> # Perform ADF unit root tests on original series and residuals
> sapply(symbolv, function(symbol) {
+   c(series=tseries::adf.test(retc[, symbol])$p.value,
+     resid=tseries::adf.test(retc[, symbol] - solved[, symbol])$p.v
+ }) # end sapply
> # Plot the residuals
> for (symbol in symbolv) {
+   plot.zoo(retc[, symbol] - solved[, symbol],
+     plot.type="single", col="blue", xlab="", ylab="")
+   legend(x="topleft", bty="n", legend=paste(symbol, "residuals"),
+     title=NULL, inset=0.05, cex=1.0, lwd=6, lty=1, col="blue")
+ } # end for
> # Perform ADF unit root test on principal component time series
> retspca <- xts(retp %*% pcad$rotation, order.by=datev)
> pcacum <- cumsum(retspca)
> adf_pvalues <- sapply(1:NCOL(pcacum), function(ordern)
+   tseries::adf.test(pcacum[, ordern])$p.value)
> # AdF unit root test on stationary time series
> tseries::adf.test(rnorm(1e5))
```

# Correlation and Factor Analysis

```

> ### Perform pair-wise correlation analysis
> # Calculate correlation matrix
> cormat <- cor(retp)
> colnames(cormat) <- colnames(retp)
> rownames(cormat) <- colnames(retp)
> # Reorder correlation matrix based on clusters
> # Calculate permutation vector
> library(corrplot)
> ordenr <- corrMatOrder(cormat, order="hclust",
+   hclust.method="complete")
> # Apply permutation vector
> cormat <- cormat[ordenr, ordenr]
> # Plot the correlation matrix
> colorv <- colorRampPalette(c("red", "white", "blue"))
> corrplot(cormat, tl.col="black", tl.cex=0.8,
+   method="square", col=colorv(8),
+   cl.offset=0.75, cl.cex=0.7,
+   cl.align.text="l", cl.ratio=0.25)
> # draw rectangles on the correlation matrix plot
> corrRect.hclust(cormat, k=NROW(cormat) %/% 2,
+   method="complete", col="red")

```

# Hierarchical Clustering Analysis

The function `as.dist()` converts a matrix representing the *distance* (dissimilarity) between elements, into a list of class "dist".

For example, `as.dist()` converts  $(1 - \text{correlation})$  to distance.

The function `hclust()` recursively combines elements into clusters based on their mutual *distance*.

First `hclust()` combines individual elements that are closest to each other.

Then it combines elements to the closest clusters, then clusters with other clusters, until all elements are combined into one cluster.

This process of recursive clustering can be represented as a *dendrogram* (tree diagram).

Branches of a *dendrogram* represent clusters.

Neighboring branches contain elements that are close to each other (have small distance).

Neighboring branches combine into larger branches, that then combine with their closest branches, etc.

```
> # Convert correlation matrix into distance object
> distancev <- as.dist(1-cormat)
> # Perform hierarchical clustering analysis
> cluster <- hclust(distancev)
> plot(cluster, ann=FALSE, xlab="", ylab="")
> title("Dendrogram representing hierarchical clustering
+ \nwith dissimilarity = 1-correlation", line=-0.5)
```

# depr: Principal Component Returns Time Series
